Long-term use of interferon- β in multiple sclerosis increases $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ $\gamma\delta$ T cells that are associated with a better outcome

Abstract

Background: We previously reported that $V\delta 2^{+}V\gamma 9^{+}$ $\gamma\delta$ T cells were significantly decreased in multiple sclerosis (MS) patients without disease-modifying therapies (untreated MS) and were negatively correlated with Expanded Disability Status Scale (EDSS) scores, suggesting protective roles of $V\delta 2^{+}V\gamma 9^{+}$ $\gamma\delta$ T cells. Interferon- β (IFN- β) is one of the first-line disease-modifying drugs for MS. However, no previous studies have reported changes in $\gamma\delta$ T cell subsets under IFN- β treatment. Therefore, we aimed to clarify the effects of the long-term usage of IFN- β on $\gamma\delta$ T cell subsets in MS patients.

Methods: Comprehensive flow cytometric immunophenotyping was performed in 35 untreated MS and 21 MS patients on IFN- β for more than 2 years (IFN- β -treated MS) including eight super-responders fulfilling no evidence of disease activity criteria, and 44 healthy controls (HCs).

Results: The percentages of $V\delta 2^{+}V\gamma 9^{+}$ cells in $\gamma\delta$ T cells were significantly lower in untreated and IFN- β -treated MS patients than in HCs. By contrast, the percentages of $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ cells in $\gamma\delta$ T cells were markedly higher in IFN- β -treated MS patients than in HCs and untreated MS patients (both $p < 0.001$). A significant negative correlation between the percentages of $V\delta 2^{+}V\gamma 9^{+}$ cells in $\gamma\delta$ T cells and EDSS scores was confirmed in untreated MS but not evident in IFN- β -treated MS. Moreover, class-switched memory B cells were decreased in IFN- β -treated MS compared with HCs ($p < 0.001$) and untreated MS patients ($p = 0.006$). Interestingly, the percentages of $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ cells in $\gamma\delta$ T cells were negatively correlated with class-switched memory B cell percentages in all MS patients ($r = -0.369$, $p = 0.005$), and the percentages of $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ cells in $V\delta 1^{-}V\delta 2^{-}$ $\gamma\delta$ T cells were negatively correlated with EDSS scores only in IFN- β super-responders ($r = -0.976$, $p < 0.001$).

Conclusions: The present study suggests that long-term usage of IFN- β increases $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ $\gamma\delta$ T cells, which are associated with a better outcome, especially in IFN- β super-responders. Thus, increased $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ cells together with decreased class-switched memory B cells may contribute to the suppression of disease activity in MS patients under IFN- β treatment.

Background

Multiple sclerosis (MS) is an inflammatory demyelinating disease of the central nervous system (CNS) mediated by autoreactive T cells [1]. T cells can be divided into $\alpha\beta$ T cells and $\gamma\delta$ T cells according to the type of T cell receptor (TCR) they express: $\alpha\beta$ T cells express TCR α and β chains while $\gamma\delta$ T cells express TCR γ and δ chains. To date, $\alpha\beta$ T cells such as interferon (IFN)- γ -secreting helper T (Th) 1 cells, interleukin (IL)-17-secreting Th17 cells, and regulatory T (Treg) cells have attracted much attention in elucidating the mechanisms of MS.

In addition, $\gamma\delta$ T cells are also assumed to be involved in the pathogenesis of various inflammatory diseases [2], although $\gamma\delta$ T cells comprise <5% of lymphocytes in the peripheral blood [3]. In MS, $\gamma\delta$ T cells are increased in the blood and cerebrospinal fluid [4], and are present in chronic active brain lesions [5–8]. We previously reported that deletion-type copy number variation (CNV) at TCR α and γ loci greatly enhanced susceptibility to MS [9]. A deletion-type CNV at the TCR α locus also covers TCR δ genes [3]. Based on these facts, we hypothesized that a deviation in TCR $\gamma\delta$ gene rearrangement contributes to the pathogenesis of MS. Recently, we conducted comprehensive flow cytometric immunophenotyping in MS patients without disease-modifying therapies (DMTs) (defined as untreated MS), and reported that percentages of V δ 2⁺ and V δ 2⁺V γ 9⁺ cells in $\gamma\delta$ T cells were decreased and that the V δ 1/V δ 2 ratio was increased compared with healthy controls (HCs) [10]. In this study, V δ 2⁺V γ 9⁺ $\gamma\delta$ T cells showed a negative correlation with disability and a positive correlation with the percentages of Treg in CD4⁺ T cells, suggesting the protective roles of V δ 2⁺V γ 9⁺ $\gamma\delta$ T cells.

IFN- β is a widely used first-line DMT for MS. IFN- β has pleiotropic effects on the peripheral immune system including the reduction of pathogenic Th1 and Th17 cells and an increase in IL-10-producing Treg cells, which are thought to be beneficial for MS [11]. In addition, IFN- β treatment reduced CD27⁺ memory B cells, which are thought to drive MS, whereas transitional B cells producing IL-10 and exerting regulatory functions were increased [12–14]. However, no previous studies have reported changes in $\gamma\delta$ T cell subsets under IFN- β treatment. Therefore, the present study investigated the phenotypic changes of $\gamma\delta$ T cell subsets by IFN- β treatment, which is associated with therapeutic effects in MS.

Methods

Study subjects

We enrolled 35 untreated MS and 21 IFN- β -treated MS patients and 44 HCs. All patients were thoroughly examined and regularly followed up at Kyushu University

Hospital, Fukuoka, Japan. Diagnoses of MS and MS subtype were based on the prevailing criteria at the commencement of the study [15]; however, all enrolled patients also fulfilled the newly published revised criteria [16]. All MS patients were in the remission phase and negative for anti-aquaporin 4 antibody. Disease severity was evaluated by the Kurtzke Expanded Disability Status Scale (EDSS) [17] and MS Severity Score (MSSS) [18]. Untreated MS patients were not under any DMTs or corticosteroids for at least 6 months prior to the immunophenotyping. IFN- β -treated MS patients received either IFN- β -1a (11 patients) or IFN- β -1b (ten patients) for more than 2 years at the time of sampling (range, 3 to 20 years; median 7.0 [interquartile range (IQR) = 5.0–10.0] years). They were then separated into two groups, a ‘no-evidence of disease activity’ (NEDA) group ($n = 8$) representing super-responders, which was defined by no relapses, no EDSS progression, and no MRI activity (no new/enlarging T2 lesions or no gadolinium-enhancing lesions) [19] at least over the preceding 2 years [20, 21], and an ‘evidence of disease activity’ (EDA) group ($n = 13$) representing partial responders, who did not fulfill the definition of NEDA based on clinical and radiographic evaluation. Untreated MS patients were also classified into NEDA and EDA groups ($n = 19$ and 13, respectively) based on their disease activity over the preceding 2 years (three patients were excluded because of insufficient clinical information of disease activity over the preceding 2 years). All patients were enrolled between March 1, 2016 and May 28, 2017. The present study was approved by the Ethical Committee of Kyushu University and conducted with written informed consent from all participants according to the World Medical Association Declaration of Helsinki.

The clinical features of all participants are summarized in Table 1. The proportion of females and age at examination did not significantly differ between untreated and IFN- β -treated MS patients, while participants in both groups of MS patients were significantly older than HCs (both $p < 0.001$). Untreated MS patients had a higher proportion of females compared with HCs ($p = 0.023$). Disease duration, EDSS scores, and MSSS at examination were comparable between untreated and IFN- β -treated MS groups. Comparisons of IFN- β -treated MS patients in the NEDA and EDA groups showed that disease duration at examination, disease duration at IFN- β initiation, duration of IFN- β treatment, EDSS scores, and MSSS at IFN- β initiation were not significantly different. Changes in EDSS and MSSS when measured at IFN- β initiation and examination (Δ EDSS and Δ MSSS, respectively) were lower in the NEDA group than in the EDA group as expected ($p = 0.003$ and 0.013, respectively, Additional file 1: Table S1), and EDSS scores and MSSS at examination tended to be

EDSS Expanded Disability Status Scale, HCs healthy controls, IFN- β interferon- β , IQR interquartile ranges, MS multiple sclerosis, MSSS MS severity score, NS not significant, PPMS primary progressive MS, RRMS relapsing-remitting MS, SPMS secondary progressive MS, w/ with

lower in the NEDA group than in the EDA group ($p = 0.062$ and 0.060 , respectively). Moreover, age at examination in both NEDA and EDA groups was older than in HCs ($p = 0.004$ and 0.010 , respectively). The clinical features of untreated MS patients in the NEDA and EDA groups were not significantly different, except for Δ EDSS and Δ MSSS, which were significantly lower in the NEDA group compared with the EDA group ($p < 0.001$, both) (Additional file 1: Table S2). A comparison between relapsing-remitting MS (RRMS) vs. progressive MS (PMS) including primary progressive MS (PPMS) and secondary progressive MS (SPMS) subtypes showed that EDSS scores and MSSS at examination were significantly higher in PMS than RRMS for both untreated and IFN- β -treated MS patients while age at examination was significantly higher in PMS than RRMS for untreated MS patients ($p = 0.043$) (Additional file 1: Table S3).

Antibodies and flow cytometric analysis

Sample preparation and detailed procedures were described previously [10]. In brief, peripheral blood mononuclear cells were collected by density gradient centrifugation using Lymphoprep tubes (Axis-shield Poc AS, Oslo, Norway) containing Ficoll-Paque (GE Healthcare, Little Chalfont, UK) and then suspended in RPMI-1640 medium (Wako, Osaka, Japan) supplemented with 10% fetal bovine serum. For intracellular staining, cell suspensions were incubated with 25 ng/ml of phorbol 12-myristate 13-acetate and 1 μ g/ml of ionomycin in the presence of 10 μ g/ml of Brefeldin A (all purchased from Sigma-Aldrich, St. Louis, MO, USA) for 4 h at 37 °C. The following fluorochrome-conjugated anti-human monoclonal antibodies were used in this study: anti-CD3

(clone: SK-7), anti-CD8 (RPA-T8), anti-CD14 (M5E2), anti-CD19 (HIB-19), anti-CD20 (2H7), anti-CD27 (M-T271), anti-CD45RA (HI100), anti-CD127 (HILL-7R-M21), anti-CCR7 (150503), anti-HLR-DR (G-46-6), anti-IgD (IA6-2), anti-IL17A (N49-653), anti-TCR V δ 2 (B6), anti-TCR V γ 9 (B3), TCR $\gamma\delta$ (B1) (BD Biosciences, Franklin Lakes, NJ, USA), and anti-CD4 (RPA-T4), anti-CD24 (MIL-5), anti-CD25 (BC96), anti-CD38 (HB-7), anti-CD3 (UCHT1), anti-IFN- γ (4S.B3), anti-IL-4 (MP4-25D2), anti-granulocyte macrophage colony-stimulating factor (GM-CSF) (BVD-21C11) (BioLegend, San Diego, CA, USA), anti-TCR V δ 1 (TS-1) (Thermo Fisher Science, Waltham, MA, USA), anti-IL-17A (eBio64DEC17), and anti-TCR $\alpha\beta$ (IP-26) (eBioscience, San Diego, CA, USA) antibodies. Stained cells were analyzed on a FACS-Verse flow cytometer (BD Biosciences). The data were analyzed using FlowJo software (Tree Star, Ashland, OR, USA). The immunophenotyping strategy for $\gamma\delta$ T cell subsets is shown in Additional file 2: Figure S1a.

Statistical analysis

Categorical variables were described by counts and percentages, and continuous and ordinal variables by median and IQRs. Demographic features of participants were compared using Fisher's exact test or the Wilcoxon test. When comparing the proportions of MS subtype between groups, a likelihood ratio chi-square test was used because it includes more than two categories. The Wilcoxon test was used to compare the percentages of each cell subtype among the two groups (RRMS vs. PMS). The Kruskal-Wallis non-parametric test was used to compare percentages among three groups (untreated MS vs. IFN- β -treated MS vs. HCs, or NEDA vs. EDA vs.

HCs). If there was statistical significance by the Kruskal-Wallis analysis, multivariate linear regression analyses adjusting for age and sex were performed for comparison between two groups, and adjusted p values (p^{adj}) are shown. Correlations among continuous scales were calculated using Spearman's rank correlation coefficient. Statistical analysis was performed using JMP[®] Pro version 14.0.0 software (SAS Institute, Cary, NC, USA). The significance level was set at $p < 0.05$.

Results

$\gamma\delta$ T cell subsets

First, we assessed differences in the percentages of $V\delta 1^+$, $V\delta 2^+$, and $V\delta 1^-V\delta 2^-$ cells in $\gamma\delta$ T cells between untreated MS, IFN- β -treated MS, and HCs. $V\delta 2^+$ and $V\delta 1^-V\delta 2^-$ cells were significantly different between groups (both $p < 0.001$, Table 2, Additional file 2: Figure S1b). The percentage of $V\delta 2^+$ $\gamma\delta$ T cells was significantly lower in untreated MS patients and IFN- β -treated MS patients compared with that in HCs ($p^{adj} = 0.047$ and $p^{adj} < 0.001$, respectively). $V\delta 2^+V\gamma 9^+$ $\gamma\delta$ T cells were also lower in both MS patient groups than in HCs ($p^{adj} = 0.043$ and $p^{adj} < 0.001$, respectively). Additionally, the percentages of $V\delta 2^+$ and $V\delta 2^+V\gamma 9^+$ $\gamma\delta$ T cells were significantly lower in IFN- β -treated MS than in untreated MS ($p^{adj} = 0.017$ and 0.016 , respectively). More interestingly, the percentage of $V\delta 1^-V\delta 2^-$ $\gamma\delta$ T cells was significantly higher in IFN- β -treated MS patients than in untreated MS and HCs ($p^{adj} = 0.002$ and $p^{adj} < 0.001$, respectively). Moreover, the percentage of $V\delta 1^-V\delta 2^-V\gamma 9^-$ $\gamma\delta$ T cells in IFN- β -treated MS patients was higher than in untreated MS patients and HCs (both $p^{adj} < 0.001$). The percentage of $V\delta 1^-V\delta 2^-V\gamma 9^+$ cells in IFN- β -treated MS patients was lower than in HCs ($p^{adj} = 0.009$). These results suggest that IFN- β increased the percentage of $V\delta 1^-V\delta 2^-$

$\gamma\delta$ T cells, especially $V\delta 1^-V\delta 2^-V\gamma 9^-$ $\gamma\delta$ T cells, and decreased the percentage of $V\delta 2^+$ $\gamma\delta$ T cells, especially $V\delta 2^+V\gamma 9^+$ $\gamma\delta$ T cells.

Cytokine production by $\gamma\delta$ T cell subsets

Next, we compared the effect of IFN- β treatment on the cytokine production of $\gamma\delta$ T cells. In $V\delta 1^+$, $V\delta 2^+$, and $V\delta 1^-V\delta 2^-$ $\gamma\delta$ T cells, the percentages of IFN- γ -producing cells were lower in both MS groups compared with HCs (Table 3), and there were no significant differences between untreated MS and IFN- β -treated MS groups.

$\alpha\beta$ T cell subsets

Next, the percentages of $\alpha\beta$ T cell subsets between MS patients and HCs were compared. In $CD4^+$ T cells, percentages of Treg cells were different among the three groups, but after adjusting for age and sex, the differences were not significant. There were no significant differences in other $CD4^+$ T cell subsets (Additional file 1: Table S4). In $CD8^+$ T cells, the percentages of naïve T cells and central memory T cells were higher in IFN- β -treated MS patients than in untreated MS patients ($p^{adj} = 0.031$ and 0.013 , respectively, Additional file 1: Table S5). When analyzing cytokine production in $\alpha\beta$ T cells, percentages of IL-17A⁺, IL-4⁺, GM-CSF⁺, and IL-17A⁺GM-CSF⁺ $CD4^+$ T cells were lower in untreated MS patients than in HCs ($p^{adj} = 0.017$, 0.011 , 0.002 , and 0.010 , respectively), and percentages of GM-CSF⁺ $CD4^+$ T cells were also lower in IFN- β -treated MS than in HCs ($p^{adj} = 0.034$, Additional file 1: Table S6). However, there were no significant differences in cytokine producing $CD4^+$ T cells between the two MS groups. The percentage of IL-17A⁺IFN- γ^+ $CD4^+$ T cells was significantly different among

the three groups, but it was not significant after adjusting for age and sex. For CD8⁺ T cells, percentages of IL-17A⁺, IFN- γ ⁺, and IL-17A⁺IFN- γ ⁺ cells were not different among the three groups.

B cell subsets

The percentage of circulating memory B cells was significantly different between groups ($p < 0.001$, Table 4). The percentages of memory B cells and class-switched memory B cells were specifically decreased in IFN- β -treated MS, but not in untreated MS patients (for memory B cells: IFN- β -treated MS vs. untreated MS, $p^{adj} = 0.009$; IFN- β -treated MS vs. HCs, $p^{adj} < 0.001$; untreated MS vs. HCs, $p^{adj} = 0.669$; for class-switched memory B cells: IFN- β -treated MS vs. untreated MS, $p^{adj} = 0.006$; IFN- β -treated MS vs. HCs, $p^{adj} < 0.001$; untreated MS vs. HCs, $p^{adj} = 0.984$). However, percentages of non-class-switched memory B cells were lower in

IFN- β -treated MS and tended to be lower in untreated MS than in HCs ($p^{adj} < 0.001$ and $p^{adj} = 0.058$, respectively) and they were not different between IFN- β -treated MS and untreated MS. There were no significant differences in the percentages of naïve B cells, transitional B cells, and plasmablasts between MS patients and HCs. Our results suggest that IFN- β therapy specifically reduces the percentage of memory B cells, especially class-switched memory B cells (Table 4).

Comparisons of the percentages of $\gamma\delta$ T cells subsets in untreated MS patients stratified to the NEDA or EDA groups

Next, we compared the percentages of $\gamma\delta$ T cell subsets between the NEDA and EDA groups in IFN- β -treated MS. The percentages of V δ 2⁺ and V δ 2⁺V γ 9⁺ $\gamma\delta$ T cells were similar in the NEDA and EDA groups but both were lower than in HCs (V δ 2⁺: NEDA vs. HCs, $p^{adj} < 0.001$;

EDA vs. HCs, p^{adj} = 0.006; V δ 2⁺V γ 9⁺: NEDA vs. HCs, p^{adj} < 0.001; EDA vs. HCs, p^{adj} = 0.005, Table 5). The percentages of V δ 1⁻V δ 2⁻ and V δ 1⁻V δ 2⁻V γ 9⁻ γ δ T cells in γ δ T cells were similar in the NEDA and EDA groups but both were higher than in HCs (V δ 1⁻V δ 2⁻: NEDA vs. HCs, p^{adj} = 0.033; EDA vs. HCs, p^{adj} < 0.001; V δ 1⁻V δ 2⁻V γ 9⁻: NEDA vs. HCs, p^{adj} = 0.011; EDA vs. HCs, p^{adj} < 0.001). The percentages of V δ 1⁻V δ 2⁻V γ 9⁺ γ δ T cells in γ δ T cells were lower in the EDA group and tended to be lower in the NEDA group than in HCs (p^{adj} = 0.022 and p^{adj} = 0.061, respectively), but they were not significantly different between NEDA and EDA groups. Regarding cytokine production, the percentages of IFN- γ -producing cells in V δ 2⁺ γ δ T cells were lower in both IFN- β -treated groups than in HCs (NEDA vs. HCs, p^{adj} = 0.003; EDA vs. HCs, p^{adj} < 0.001) and those in V δ 1⁺ and V δ 1⁻V δ 2⁻ γ δ T cells were lower only in the EDA group compared with HCs (p^{adj} = 0.001 and p^{adj} < 0.001, respectively). Moreover, IFN- γ -producing V δ 1⁻V δ 2⁻ γ δ T cells were significantly lower in the EDA group than in the NEDA group (p^{adj} = 0.033, Additional file 1: Table S7).

Differences in B cell subsets between NEDA and EDA groups in IFN- β -treated MS

Comparisons of B cell subsets between the NEDA and EDA groups in IFN- β -treated MS and HCs showed that the percentages of memory B cells, class-switched memory B cells, and non-class-switched B cells were lower in both IFN- β -treated MS groups than in HCs (memory B: NEDA vs. HCs, p^{adj} = 0.009; EDA vs. HCs, p^{adj} < 0.001; class-switched memory B: NEDA vs. HCs, p^{adj} = 0.017; EDA vs. HCs, p^{adj} < 0.001; non-class-switched B cells: NEDA vs. HCs, p^{adj} = 0.076; EDA vs. HCs, p^{adj} = 0.002,

Table 6), but the percentages of these memory B cell subsets in the NEDA and EDA groups were comparable. The percentages of other B cell subsets were not different between groups.

Relationship between γ δ T and Treg cell subsets

Consistent with our previous study [10], positive correlations between the percentages of V δ 2⁺ and Treg cells in T cells, and the percentages of V δ 2⁺V γ 9⁺ γ δ T cells and Treg cells in T cells were specifically found in HCs (V δ 2⁺: r = 0.328, p = 0.030; and V δ 2⁺V γ 9⁺: r = 0.336, p = 0.026, respectively) but not in untreated MS and IFN- β -treated MS (Fig. 1).

Association between γ δ T cell subsets and disease severity in MS patients

Additionally, we assessed the association between γ δ T cells and disability in MS patients. As previously shown [10], the percentages of V δ 2⁺ and V δ 2⁺V γ 9⁺ cells in γ δ T cells had significant negative correlations with EDSS scores in untreated MS patients (V δ 2⁺: r = -0.366, p = 0.031; and V δ 2⁺V γ 9⁺: r = -0.361, p = 0.033), while such correlations were lost in IFN- β -treated MS patients (V δ 2⁺: p = 0.053; and V δ 2⁺V γ 9⁺: p = 0.068, Fig. 2). Even though IFN- β -treated MS patients were divided to NEDA and EDA groups, these cells were not associated with EDSS scores and MSSS. However, the percentages of V δ 1⁻V δ 2⁻V γ 9⁺ cells in γ δ T cells had a strong positive correlation with EDSS scores and MSSS only in the NEDA group (EDSS: r = 0.903, p = 0.002; and MSSS: r = 0.905, p = 0.002), but such correlations were not observed in the EDA group (Fig. 3a–d). Moreover, the proportion of V δ 1⁻V δ 2⁻V γ 9⁻ cells in V δ 1⁻V δ 2⁻ γ δ T cells

were negatively correlated with EDSS scores and MSSS in the NEDA group (EDSS: $r = -0.976$, $p < 0.001$; and MSSS: $r = 0.881$, $p = 0.004$), but not the EDA group (Fig. 3e–h). These data suggest that increased V δ 1⁻V δ 2⁻V δ 9⁻ $\gamma\delta$ T cells induced by the long-term use of IFN- β are associated with a better outcome in IFN- β super-responders.

Association between B cell subsets and disease severity in MS patients treated by IFN- β

When we examined the association between B cell subsets and disease severity, the percentages of memory B cells and class-switched memory B cells were positively associated with EDSS scores only in the EDA group of IFN- β -treated MS patients ($r = 0.722$, $p = 0.005$; $r = 0.719$, $p = 0.006$, respectively), but not in the NEDA group ($p = 0.601$ and 0.518 , respectively) (Fig. 4).

Relationship between $\gamma\delta$ T and B cell subsets

Interestingly, we observed the percentages of V δ 1⁻V δ 2⁻ cells and V δ 1⁻V δ 2⁻V γ 9⁻ cells in $\gamma\delta$ T cells were

negatively correlated with class-switched memory B cells when analyzing all MS patients (V δ 1⁻V δ 2⁻: $r = -0.373$, $p = 0.005$; and V δ 1⁻V δ 2⁻V γ 9⁻: $r = -0.369$, $p = 0.005$, Fig. 5).

Comparison of untreated MS patients in the NEDA and EDA groups

The percentages of each $\gamma\delta$ T cell subset were similar in untreated MS patients in the NEDA and EDA groups (Additional file 1: Table S8). The percentage of plasmablasts, but not other B cell subsets, were higher in the EDA group than in the NEDA group ($p^{\text{adj}} = 0.008$) (Additional file 1: Table S9). The proportion of V δ 1⁻V δ 2⁻V γ 9⁻ cells in V δ 1⁻V δ 2⁻ $\gamma\delta$ T cells was not associated with the EDSS score nor MSSS in the NEDA and EDA groups (Additional file 2: Figure S2), although the percentage of V δ 1⁻V δ 2⁻V γ 9⁺ cells in $\gamma\delta$ T cells had a negative correlation with EDSS score and MSSS in the NEDA group (EDSS: $r = -0.514$, $p = 0.024$; and MSSS: $r = -0.593$, $p = 0.008$) but not in the EDA group. Memory B cell and

Differences in T and B cell subsets between RRMS and PMS

Finally, we compared the percentages of T and B cell subsets between RRMS and PMS (Additional file 1: Tables S10–S15). In untreated MS patients, the percentages of naïve T cells in CD4⁺ T cells and V $\delta 1^-$ V $\delta 2^-$ V $\gamma 9^+$ cells in $\gamma\delta$ T cells were higher and the percentage of effector memory T cells in CD4⁺ T cells was lower in RRMS than in PMS ($p = 0.002$, 0.050, and 0.004, respectively). Otherwise, no significant difference in any subsets was found between RRMS and PMS. In IFN- β -treated MS patients, no significant difference was found between RRMS and PMS, except that the percentages of naïve B cells and transitional B cells were significantly higher in RRMS than in PMS ($p < 0.001$ and $p = 0.015$,

respectively). Furthermore, in RRMS, the percentages of naïve B cells and transitional B cells were higher in IFN- β -treated MS patients than in untreated MS patients ($p^{adj} = 0.010$ and 0.001, respectively). These findings suggest that IFN- β treatment increased the percentage of V $\delta 1^-$ V $\delta 2^-$ V $\gamma 9^-$ $\gamma\delta$ T cells irrespective of clinical subtype.

Discussion

Our comprehensive immunophenotyping study of peripheral blood lymphocytes found that prominent changes occurred in $\gamma\delta$ T cells and B cell subsets upon IFN- β treatment. This is the first report of a marked increase in V $\delta 1^-$ V $\delta 2^-$ V $\gamma 9^-$ $\gamma\delta$ T cells and decrease in V $\delta 2^+$ $\gamma\delta$ T cells. A previous study reported a decrease in class-switched memory B cells by IFN- β [13, 14], which is confirmed in the present study. The increase of transitional B cells by IFN- β in RRMS [12] was also confirmed when analyzing RRMS patients separately. In IFN- β -treated MS

patients, the percentages of naïve and transitional B cells were significantly higher in RRMS than in PMS. These findings are also comparable with previous reports describing an increase in naïve and transitional B cells and a decrease in memory B cells by IFN- β treatment in MS consisting of exclusively or mostly RRMS patients [12–14, 22]. It was also reported that the percentage of naïve T cells tended to decrease and that of memory T cells tended to increase in SPMS compared with RRMS [23]. Such differences by MS subtype are partly explained by the higher thymic export of naïve $CD4^+$ T cells in RRMS than in PPMS [24]. In addition, naïve T cells were negatively associated and memory T cells were positively associated with age [23, 25]. The higher age at examination in PMS than RRMS in our cohort may also be partly responsible for the increase of effector memory T cells and decrease of naïve T cells in PMS. Importantly, effects of IFN- β on $V\delta 1^-V\delta 2^-V\gamma 9^-$ $\gamma\delta$ T cells were observed, regardless of the clinical subtype including RRMS and PMS. In addition, these changes in $V\delta 1^-V\delta 2^-V\gamma 9^-$ $\gamma\delta$ T cells were not observed in untreated MS patients even after

stratification to NEDA and EDA groups, further supporting the relationship of changes in $V\delta 1^-V\delta 2^-V\gamma 9^-$ $\gamma\delta$ T cell percentages by IFN- β treatment.

When we designed the present study, we anticipated an improvement in the low percentages of $V\delta 2^+V\gamma 9^+$ $\gamma\delta$ T cells observed in untreated MS [10] by IFN- β treatment; however, we unexpectedly found that IFN- β increased $V\delta 1^-V\delta 2^-V\gamma 9^-$ cell percentages in $\gamma\delta$ T cells but did not reverse the decrease of $V\delta 2^+V\gamma 9^+$ cells nor the loss of a positive correlation between $V\delta 2^+V\gamma 9^+$ $\gamma\delta$ T cells and Treg cells seen in HCs. $V\delta 1^-V\delta 2^-V\gamma 9^-$ $\gamma\delta$ T cells in MS had a negative correlation with class-switched memory B cells, which was specifically reduced by IFN- β treatment. In the super-responder (NEDA) group of IFN- β -treated MS, $V\delta 1^-V\delta 2^-V\gamma 9^-$ $\gamma\delta$ T cells had a negative correlation with EDSS scores. These findings suggest that $V\delta 1^-V\delta 2^-V\gamma 9^-$ $\gamma\delta$ T cells upregulated by IFN- β play a protective role against MS and that $V\delta 2^+V\gamma 9^+$ $\gamma\delta$ T cells may not play a major role in the treatment effects of IFN- β .

The majority of $V\delta 1^-V\delta 2^-$ $\gamma\delta$ T cells express the $V\delta 3$ TCR chain [26, 27]. $V\delta 3$ $\gamma\delta$ T cells are normally the

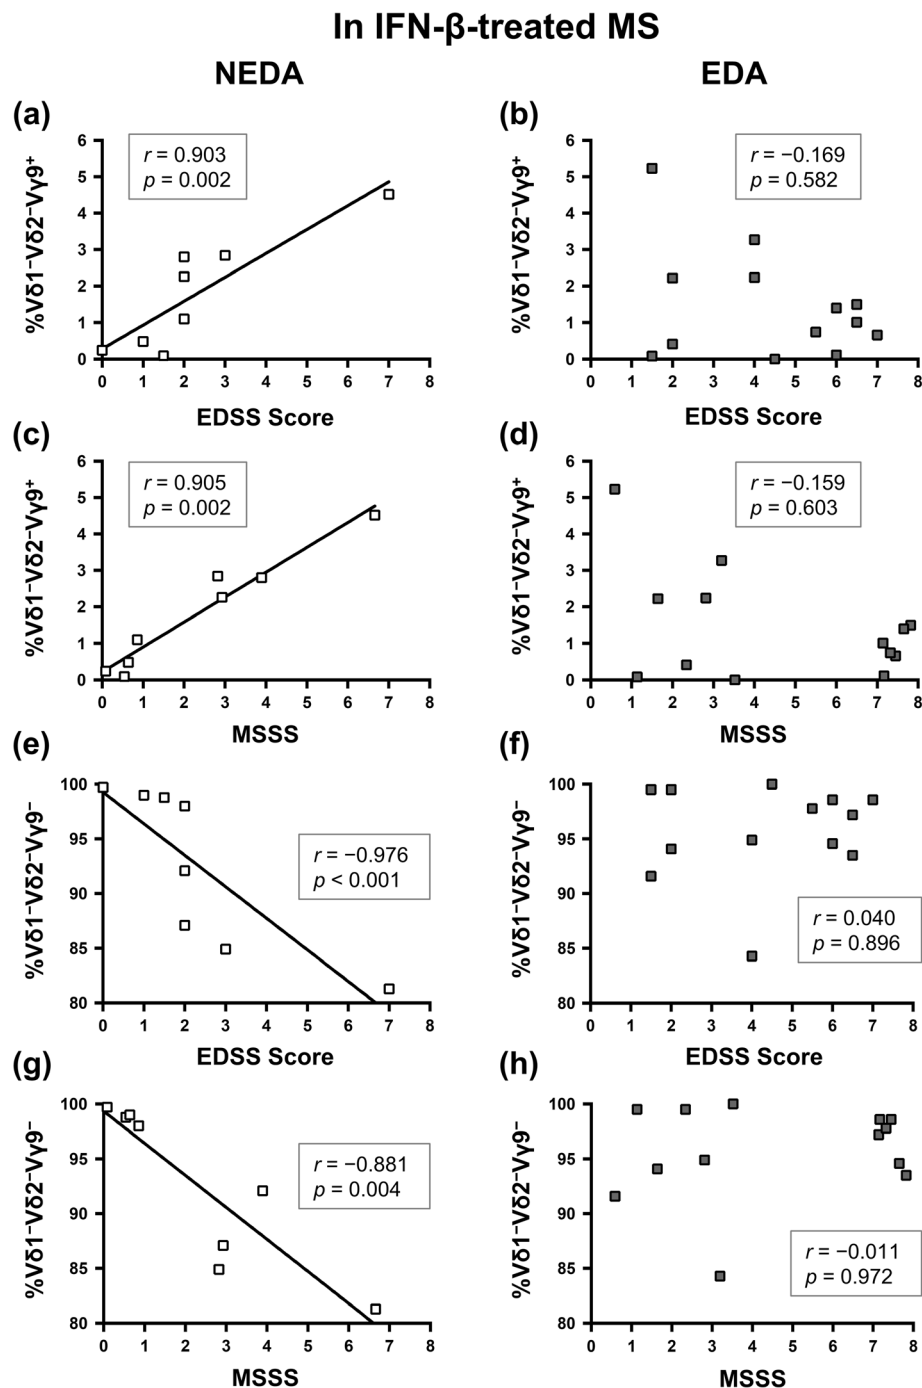

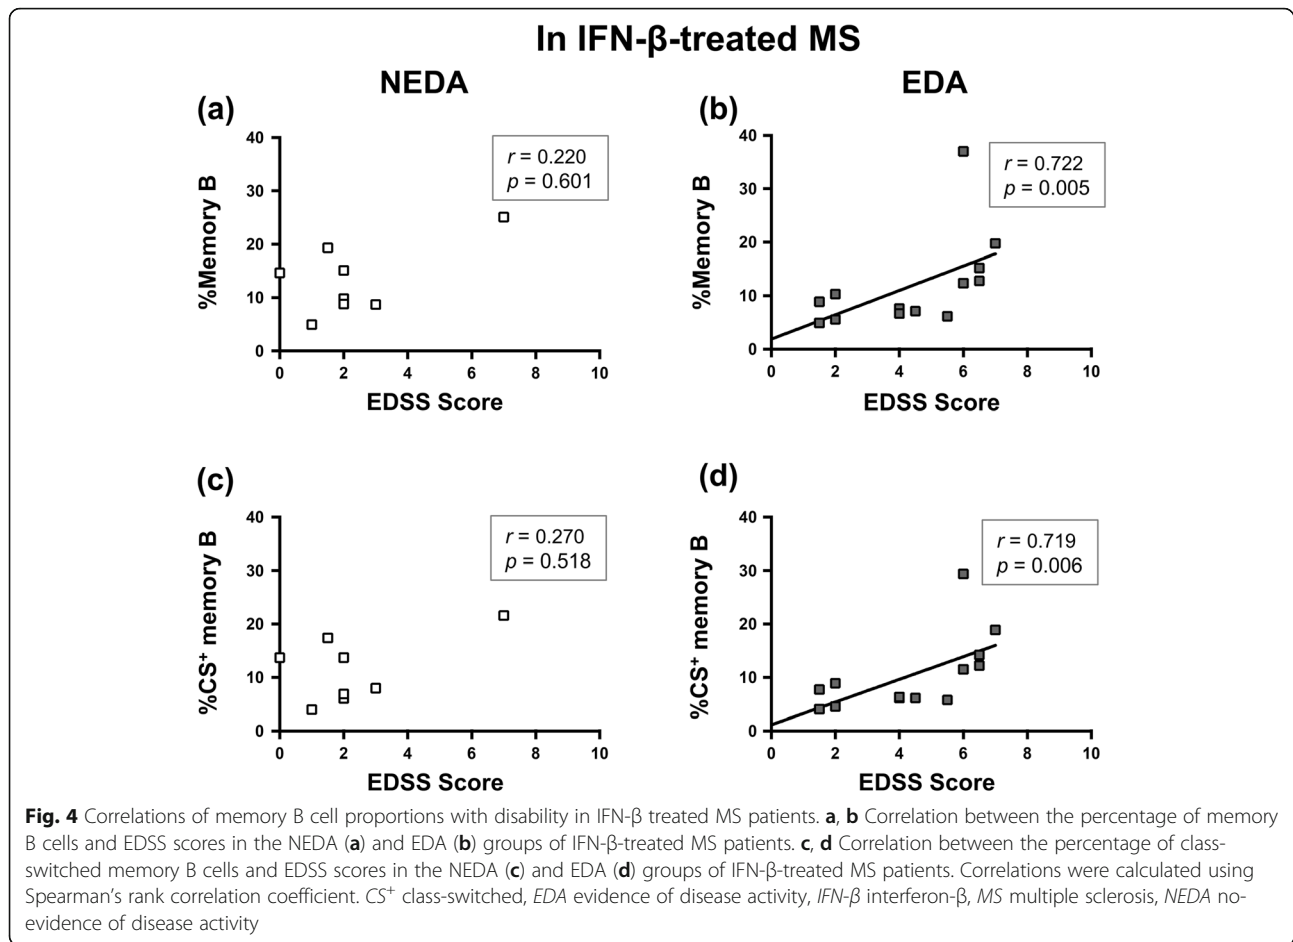

Fig. 3 Correlations between the percentages of $\gamma\delta$ T cell subsets and disability in IFN- β -treated MS patients. **a–d** Correlation between the percentage of $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{+}$ cells in $\gamma\delta$ T cells and EDSS scores (**a, b**) or MSSS (**c, d**) at examination in NEDA (**a, c**) and EDA (**e, f**) groups of IFN- β -treated MS patients. **e–h** Correlation between the percentage of $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ cells in $V\delta 1^{-}V\delta 2^{-}$ $\gamma\delta$ T cells and EDSS scores (**e, f**) or MSSS (**g, h**) at examination in NEDA (**e, g**) and EDA (**f, h**) groups of IFN- β -treated MS patients. Correlations were calculated using Spearman's rank correlation coefficient. *EDA* evidence of disease activity, *EDSS* Expanded Disability Status Scale, *IFN- β* interferon- β , *MS* multiple sclerosis, *MSSS* multiple sclerosis severity score, *NEDA* no-evidence of disease activity

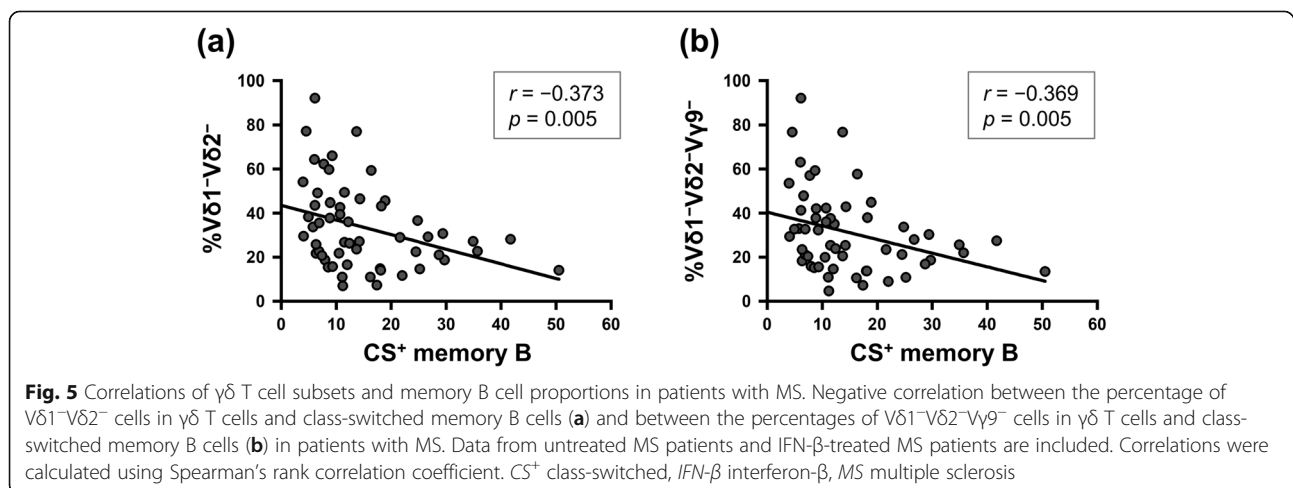

third most common $\gamma\delta$ T cell subset in peripheral blood lymphocytes and account for only $\sim 0.5\%$ of circulating T cells [26, 28], although they are enriched in the gut

[29] and liver [28]. $V\delta 3$ $\gamma\delta$ T cells recognize human leukocyte antigen (HLA)-A2 [30] and CD1d [26], although the specific antigen molecules involved remain

unknown. Upon activation, V δ 3 $\gamma\delta$ T cells produce IFN- γ , IL-4, and IL-17, thereby promoting Th1, Th2, and Th17 cell differentiation, respectively [31]. Expansion of V δ 1⁻V δ 2⁻ or V δ 3 $\gamma\delta$ T cells in the peripheral blood has seldom been reported; indeed, it was only observed upon cytomegalovirus reactivation after renal and stem cell

transplantation [32, 33]. An alteration of V δ 1⁻V δ 2⁻ or V δ 3 $\gamma\delta$ T cells has not been described in MS. Among the V δ 1⁻V δ 2⁻ cell subset increased by IFN- β treatment, V δ 1⁻V δ 2⁻V γ 9⁻ cells were increased but V δ 1⁻V δ 2⁻V γ 9⁺ cells were decreased. V δ 1⁻V δ 2⁻V γ 9⁻ cells had a negative correlation with EDSS scores, whereas V δ 1⁻V δ 2⁻V γ 9⁺

cells had a positive correlation with them. Because $V\gamma 9^+$ subsets are functionally distinct from their $V\gamma 9^-$ counterparts [34], these findings suggest that $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells but not $V\delta 1^-V\delta 2^-V\gamma 9^+$ cells are related to the beneficial effects of IFN- β on MS.

Although the exact roles of $V\delta 3 \gamma\delta$ T cells under normal physiological conditions remain to be elucidated, they are assumed to have similar immunomodulatory functions to invariant natural killer T (iNKT) cells that recognize glycolipid antigens presented by CD1d molecules [35, 36]. In various animal models of autoimmune/inflammatory diseases, including experimental autoimmune encephalomyelitis, an animal model of MS, iNKT cells prevent inflammation [35–38]. Likewise, $V\delta 3 \gamma\delta$ T cells regulated adaptive immunity via the production of multiple cytokines [26]. In our study, in $V\delta 1^-V\delta 2^-$ cells, IFN- γ -producing cells were significantly decreased while IFN- γ IL-17 $^-$ cells were increased in the IFN- β -treated MS patients. Thus, it is possible that $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells producing cytokines other than IFN- γ and IL-17 are associated with protection against MS by immunomodulatory effects in IFN- β -treated patients. The specific cytokines and functions related to these cells should be investigated in future studies.

Interestingly, we found a negative correlation of $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells with class-switched memory B cells in MS patients. In MS, the importance of B cells has become increasingly evident by the recent clinical trial results showing anti-CD20 monoclonal antibodies (rituximab, ocrelizumab, and ofatumumab) targeting B cells, but not plasma cells, are highly effective at reducing relapse and disability progression in MS [39–41]. Because the number of B cells but not the total antibody level decreased in parallel with the decrease in relapse rate [39–41], it is considered that B cell-T cell interactions, such as antigen presentation and proinflammatory cytokine secretion by B cells, are crucial in MS pathogenesis. In the present study, we found that IFN- β treatment markedly decreased class-switched memory B cells, which is consistent with previous reports demonstrating that IFN- β specifically reduced pathogenic memory B cells in MS [13, 14].

In our study, among IFN- β users, a positive correlation of class-switched memory B cells with EDSS scores was evident in the EDA group showing a wide range of responses. Presumably, the reduction of class-switched memory B cells by IFN- β treatment is partly responsible for the beneficial effects of IFN- β . The positive correlation between class-switched memory B cells and EDSS scores was not observed in super-responders to IFN- β (NEDA group), possibly because of plateau effects. $V\delta 3 \gamma\delta$ T cells induce the maturation and IgM secretion of B cells but do not induce class switching to IgG, IgA, or

IgE [31]. Rather, $V\delta 3 \gamma\delta$ T cells exerted cytotoxic functions against CD1d-bearing target cells upon the recognition of CD1d molecules [26, 33]. Because B cells express high surface levels of CD1d [42, 43], they might be a target of $V\delta 3 \gamma\delta$ T cells. In addition, we found a negative correlation between $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells and class-switched memory B cells in MS patients, indicating that $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells might contribute to the attenuation of disease activity by killing class-switched memory B cells that are pathogenic in MS.

The present study had several limitations. First, we did not use an anti- $V\delta 3$ TCR antibody for immunophenotyping because of the unavailability of a specific antibody. Although the majority of $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells harbor $V\delta 3$ TCR [26, 27], future studies using anti- $V\delta 3$ TCR antibody would be desirable to confirm our results. Second, the characterization of $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells was insufficient. More extensive assays on cytokine production and functional assays for the cytotoxicity of $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells are necessary to elucidate the roles of these cells. Third, the mechanism of how IFN- β increases the number of $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells remains unclear. However, $V\delta 3 \gamma\delta$ T cells have been shown to expand upon reactivation of chronic viral infections, such as cytomegalovirus [32, 33], which involve innate immune responses including type I IFN [44–46]. Thus, IFN- β may facilitate the expansion of $V\delta 1^-V\delta 2^-V\gamma 9^-$ cells by a mechanism similar to that during persistent viral infection. Fourth, we did not examine anti-IFN- β neutralizing antibody status in the present study. In our cohort, IFN- β -1a was administered to 11 patients and IFN- β -1b to ten patients. Anti-IFN- β neutralizing antibodies are reported to develop for IFN- β -1a in approximately 5% and for IFN- β -1b in approximately 25% of MS patients [47]; therefore, two to three patients on IFN- β in our cohort may have had anti-IFN- β neutralizing antibodies. Thus, 15–23% of the 13 EDA patients may have possessed them at the time of the flow cytometry, which may have influenced the comparison between NEDA and EDA groups. However, the percentages of $V\delta 1^-V\delta 2^-V\gamma 9^- \gamma\delta$ T cells were not significantly different between the EDA and NEDA groups while the EDA group still demonstrated a significantly higher percentage of $V\delta 1^-V\delta 2^-V\gamma 9^- \gamma\delta$ T cells than the HC group. Therefore, we believe that the potential effects of anti-IFN- β neutralizing antibodies on $\gamma\delta$ T cell subsets would not severely distort the present results, although this point should be investigated in future studies. Another limitation of this study is the absence of serum cytokine concentrations. We focused on specific immune cells, especially $\gamma\delta$ T cells, and their cytokine production. $\gamma\delta$ T cells comprise < 5% of lymphocytes in the peripheral blood [3], and the number of $\gamma\delta$ T cells producing each cytokine is inconsistent with serum cytokine levels [48]. Given that serum cytokine

concentration does not provide information about the source cell types, we did not measure serum cytokine levels in each patient. The correlation between serum cytokine concentrations and $\gamma\delta$ T subsets should be studied in the future. Finally, because the numbers of enrolled patients in the NEDA and EDA groups consisting of IFN- β -treated MS patients were relatively small in this study, our findings should be confirmed in a future study using a larger sample size.

Conclusions

Extensive flow cytometric immunophenotyping of peripheral blood lymphocytes from untreated and persistently IFN- β -treated MS patients revealed that the long-term usage of IFN- β increased the percentages of $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ $\gamma\delta$ T cells and decreased the percentages of class-switched memory B cells without a major influence on other T and B lymphocyte subsets, which may contribute to the attenuation of disease activity. Because increased $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ cells were associated with a better outcome, especially in MS patients fulfilling NEDA under IFN- β treatment, $V\delta 1^{-}V\delta 2^{-}V\gamma 9^{-}$ cells might be a target for the therapeutic immunomodulation of MS.

CNS: : Central nervous system;; CNV: : Copy number variation;; DMT: : Disease-modifying therapy;; EDA: : Evidence of disease activity;; EDSS: : Expanded Disability Status Scale;; GM-CSF: : Granulocyte macrophage

colony-stimulating factor;; HCs: : Healthy controls;; HLA: : Human leukocyte antigen;; IFN: : Interferon;; IL: : Interleukin;; iNKT: : Invariant natural killer T;; IQR: : Interquartile range;; MS: : Multiple sclerosis;; MSSS: : Multiple Sclerosis Severity Score;; NEDA: : No-evidence of disease activity;; PMS: : Progressive multiple sclerosis;; RRMS: : Relapsing-remitting multiple sclerosis;; TCR: : T cell receptor;; Th: : Helper T;; Treg: : Regulatory T

Acknowledgements

The authors thank all patients and healthy participants for providing peripheral blood samples. We thank J. Ludovic Croxford, PhD, from Edanz Group (www.edanzediting.com/ac) for English proofreading of a draft of this manuscript.

Authors' contributions

GM performed experiments, analyzed data, and wrote the manuscript. MW collected data, analyzed and interpreted data, and wrote the manuscript. KS conceived and designed the study, performed experiments, and analyzed data. YN, KM, TM, NI, and RY collected and interpreted data. YY contributed to the design and implementation of the experiments and interpreted data. JK conceived and designed the study, interpreted data and wrote the manuscript. All authors read and approved the final manuscript.

Funding

This study was supported in part by a research grant from the Japanese Multiple Sclerosis Society, by a Health and Labour Sciences Research Grant on Intractable Diseases [H26-Nanchitou (Nan)-Ippan-043, H29-Nanchitou (Nan)-Ippan-043] from the Ministry of Health, Labour and Welfare, Japan, and by grants from JSPS KAKENHI (Grant Nos. 15K09341, 16H02657, 17K16124, 17K16125 and 18K07529), Japan.

Availability of data and materials

The datasets generated and/or analyzed during the present study will be available from the corresponding author upon reasonable request based on the guidelines of the Ethics Committee of Kyushu University.

Ethics approval and consent to participate

The study received ethical approval from the Ethics Committee of Kyushu University (approval number: 575-04), and written informed consent was obtained from all participants.

Consent for publication

Not applicable.

Competing interests

GM, KM, and YY declare that they have no competing interests. MW received grant support from Japan Society for the Promotion of Science (JSPS) KAKENHI and GlaxoSmithKline KK. KS received research grants from JSPS KAKENHI and the Japanese Multiple Sclerosis Society. NI received grant support from JSPS KAKENHI, Mitsubishi Tanabe Pharma, Osoegawa Neurology Clinic, Bayer Yakuhin, Ltd., and Japan Blood Products Organization. YN received grant support from JSPS KAKENHI, Mitsubishi Tanabe Pharma, Bayer Yakuhin, Ltd., and Japan Blood Products Organization. TM received grant support from JSPS KAKENHI, and received speaker honoraria payments from Mitsubishi Tanabe Pharma, Takeda Pharmaceutical Company, and Biogen Japan. JK received grant support from the Ministry of Health, Labour, and Welfare, Japan, the Ministry of Education, Culture, Sports, Science and Technology of Japan, JSPS KAKENHI and the Japan Agency for Medical Research and Development, AMED, Japan, and received consultant fees, speaking fees, and/or honoraria from Novartis Pharma, Mitsubishi Tanabe Pharma, Boehringer Ingelheim, Teijin Pharma, Takeda Pharmaceutical Company, Otsuka Pharmaceutical, Astellas Pharma, Pfizer Japan, and Eisai. The other authors have no conflicts of interest to declare.

Publisher's Note

Springer Nature remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.
